Distributed Systems
05. Clock Synchronization

Synchronization
Synchronization covers interactions among distributed processes

<table>
<thead>
<tr>
<th>Synchronization</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Clocks</td>
<td>Identifying when something happened</td>
</tr>
<tr>
<td>Mutual exclusion</td>
<td>Only one entity can do an operation at a time</td>
</tr>
<tr>
<td>Leader election</td>
<td>Who coordinates activity?</td>
</tr>
<tr>
<td>Message consistency</td>
<td>Does everyone have the same view of events?</td>
</tr>
<tr>
<td>Agreement</td>
<td>Can everyone agree on a proposed value?</td>
</tr>
</tbody>
</table>

All of these are trivial in non-distributed systems
All of these are tricky in distributed systems

Why?
• Allow a process to identify "now" in a way that's consistent with other processes on other systems
• Temporal ordering of events from concurrent processes
  – Example: replication & identifying latest versions
    • Last writer wins or latest version wins

Simple approach to replication

P0       Data store
Replica data store
P1

P0       Data store
Replica data store
P1

Inconsistent replica!
Simple approach to replication

Send a time stamp with each modification request
Only newer timestamps can override older data

Logical vs. physical clocks

• Physical clocks keep time of day
  – Consistent across systems

• Logical clock keeps track of event ordering
  – among related (causal) events

Problem: Get two systems to agree on time

• Why is it hard?
  – Two clocks hardly ever agree
  – Quartz oscillators oscillate at slightly different frequencies

• Clocks tick at different rates
  – Create ever-widening gap in perceived time
  – Clock Drift

• Difference between two clocks at one point in time
  – Relative offset

• Short-term variation in frequency
  – Jitter

• Also note: astronomical time vs. relative time
  – Time of day vs. count of seconds from epoch

Dealing with drift

Not good idea to set a clock back
  – Illusion of time moving backwards can confuse message ordering
  and software development environments

Go for gradual clock correction

If fast:
  Make the clock run slower until it synchronizes

If slow:
  Make the clock run faster until it synchronizes

Dealing with drift

The OS can do this:

1. Redefine the rate at which system time is advanced with each interrupt
   or
2. Read the counter but compensate for drift

Adjustment changes slope of system time:

Linear compensation function
Compensating for a fast clock

UTC time, t

Computer's time, C

Linear compensation function applied

Resynchronizing

After synchronization period is reached
- Resynchronize periodically
  - Successive application of a second linear compensating function can bring us closer to true slope

Long-term clock stability is not guaranteed
The system clock can still drift based on changes in temperature, pressure, humidity, and age of the crystal

Keep track of adjustments and apply continuously
- e.g., BSD `adjtimex` & Linux `adjtimex` system calls and `hwclock` command

Going to sleep

- RTC keeps on ticking when the system is off (or sleeping)
- OS cannot apply correction continually
- Estimate drift on wake-up and apply a correction factor

Getting accurate time

- Attach GPS receiver to each computer
  - Accurate to ~ 40 ns
- Not practical solution for every machine
  - Cost, power, convenience, environment
  - Accuracy gets worse near buildings, bridges, trees, …

Synchronize from a time server

Simplest synchronization technique
- Send a network request to obtain the time
- Set the time to the returned value

Does not account for network or processing latency
Cristian’s algorithm

Compensate for delays
   - Note times:
     • request sent: \( T_0 \)
     • reply received: \( T_1 \)
   - Assume network delays are symmetric

\[
T_{\text{new}} = T_{\text{server}} + \frac{T_1 - T_0}{2}
\]

Error bounds

If the minimum message transit time \( T_{\text{min}} \) is known:

Place bounds on accuracy of result

\[
\text{range} = T_1 - T_0 - 2T_{\text{min}}
\]

\[
\text{accuracy of result} = \pm \frac{T_1 - T_0 - T_{\text{min}}}{2}
\]

Cristian’s algorithm: example

- Send request at 5:08:15.100 \( (T_0) \)
- Receive response at 5:08:15.900 \( (T_1) \)
  - Response contains 5:09:25.300 \( (T_{\text{server}}) \)
- Elapsed time is \( T_1 - T_0 \)
  
  \[
  5:08:15.900 - 5:08:15.100 = 800 \text{ ms}
  \]
- Best guess: timestamp was generated 400 ms ago
- Set time to \( T_{\text{server}} + \text{elapsed time} \)
  
  \[
  5:09:25.300 + 400 = 5:09:25.700
  \]

Note:

\[
1000 \text{ ms} = 1 \text{ s}
\]

\[
1000000 \mu\text{s} = 1\text{s}
\]

Error = \[
\pm \frac{900 - 100}{2} - 200 = \pm \frac{800}{2} - 200 = \pm 200
\]
Berkeley Algorithm

- Gusella & Zatti, 1989
- Assumes no machine has an accurate time source
- Obtains average from participating computers
- Synchronizes all clocks to a fault-tolerant average

Berkeley Algorithm: example

1. Request timestamps from all slaves

2. Compute fault-tolerant average:
   \[
   \text{Suppose } \max \partial = 0.45 \quad \text{then } \frac{3:25 + 2:50 + 3:00}{3} = 3:05
   \]

3. Send offset to each client

Network Time Protocol, NTP

- 1991, 1992
  - Internet Standard, version 3: RFC 1305
- June 2010
  - Internet Standard, version 4: RFC 5905-5908
  - IPv6 support
  - Improve accuracy to tens of microseconds
  - Dynamic server discovery

NTP Goals

- Enable clients across Internet to be accurately synchronized to UTC despite message delays
  - Use statistical techniques to filter data and gauge quality of results
- Provide reliable service
  - Survive lengthy losses of connectivity
  - Redundant paths
  - Redundant servers
- Provide scalable service
  - Enable huge numbers of clients to synchronize frequently
  - Offset effects of clock drift
- Provide protection against interference
  - Authenticate source of data
NTP servers
Arranged in strata
- Stratum 0 = master clock
- 1st stratum: systems connected directly to accurate time source
- 2nd stratum: systems synchronized from 1st stratum systems
- ...
- 15th stratum: systems synchronized from 14th stratum systems

Synchronization Subnet

NTP Synchronization Modes

Multicast mode
- for high speed LANs
- Lower accuracy but efficient

Procedure call mode
- Cristian’s algorithm

Symmetric mode
- Peer servers can synchronize with each other to provide mutual backup
  - Usually used with stratum 1 & 2 servers
  - Pair of servers retain data to improve synchronization over time

All messages are delivered unreliably with UDP (port 123)

NTP Clock Quality
• Precision
  - Smallest increase of time that can be read from the clock
• Jitter
  - Difference in successive measurements
  - Due to network delays, OS delays, and clock oscillator instability
• Accuracy
  - How close is the clock to UTC?

NTP messages
• Procedure call and symmetric mode
  - Messages exchanged in pairs: request & response
• Time encoded as a 64 bit value:
  - Divide by 2^32 to get the number of seconds since Jan 1 1900 UTC
• NTP calculates:
  - Offset for each pair of messages (θ)
  - Estimate of time offset between two clocks
  - Delay (δ)
    - Travel time: ½ of total delay minus remote processing time
    - Dispersion
      - Maximum offset error relative to reference clock
• Use this data to find preferred server:
  - Probe multiple servers – each several times
  - Pick lowest dispersion … at the lowest stratum if tied

SNTP
Simple Network Time Protocol
- Based on Unicast mode of NTP – subset of NTP, not new protocol
- Operates in multicast or procedure call mode
- Recommended for environments where server is root node and client is leaf of synchronization subnet
- Root delay, root dispersion, reference timestamp ignored

v3 RFC 2030, October 1996
v4 RFC 5905, June 2010

SNTP Example

\[
\begin{align*}
\delta &= (T_4 - T_1) - (T_3 - T_2) \\
\text{Time offset:} &= \frac{(T_4 - T_1) + (T_3 - T_2)}{2}
\end{align*}
\]
Key Points: Physical Clocks

- Cristian’s algorithm & SNTP
  - Set clock from server
  - But account for network delays
  - Error: uncertainty due to network/processor latency
    - Errors are additive
    - Example: ±10 ms and ±20 ms = ±30 ms
  - Adjust for local clock drift
    - Linear compensating function

PTP: IEEE 1588 Precision Time Protocol

- Designed to synchronize clocks on a LAN to sub-microsecond precision
  - Designed for LANs, not global: low jitter, low latency
  - Timestamps ideally generated at the MAC or PHY layers to minimize delay and jitter
- Determine master clock
  - Use a Best Master Clock algorithm to determine which clock in the network is most precise
  - Other clocks become slaves
- Two phases in synchronization
  1. Offset correction
  2. Delay correction
PTP: Choose the “best” clock

Best Master Clock
- Distributed election based on properties of clocks
- Criteria from highest to lowest:
  - Priority 1 (admin-defined hint)
  - Clock class
  - Clock accuracy
  - Clock variance: estimate of stability based on past syncs
  - Priority 2 (admin-defined hint #2)
  - Unique ID (tie-breaker)

PTP: Master initiates sync

Master initiates the protocol by sending a sync message containing a timestamp.
Slave timestamps arrival with a timestamp from its local clock.
Offset + Delay = T₂ - T₁

PTP: Send delay request

Slave needs to figure out the network delay. Send a delay request.
Note the time it was sent.

PTP: Receive delay response

Master marks the time of arrival and returns it in a delay response.
Delay response = Delay - Offset = T₄ - T₃

PTP: Slave computes offset

master_slave_difference = T₂ - T₁ = delay + offset
slave_master_difference = T₄ - T₂ = delay - offset
master_slave_difference - slave_master_difference = 2(offset)
T₂ - T₁ - T₄ + T₃ = 2(offset)
offset = (T₂ - T₁ - T₄ + T₃) / 2

NTP vs. PTP

- Range
  - NTP: nodes widely spread out on the Internet
  - PTP: local area networks

- Accuracy
  - NTP usually several milliseconds on WAN
  - PTP usually sub-microsecond on LAN
The end
